Abstract. A new statistical based model approach to characterize a user's behavior in an Internet access link is presented. The real patterns of Internet traffic in a heterogeneous Campus Network are studied. We find three clearly different patterns of individual user's behavior, study their common features and group particular users behaving alike in three clusters. This allows us to build a probabilistic mixture model, that can explain the expected global behavior for the three different types of users. We discuss the implications of this emergent phenomenology in the field of multi-agent complex systems.

Keywords: Internet traffic, emergent and collective behavior, multi-agent systems.

1 Introduction

One of the main objectives of Traffic Analysis is to identify predictive models. Models are so important because they make available practical tools (such as traffic simulators) that are widely required by TelCos (Telecommunication Companies) in core areas such as Network Engineering and Marketing. In addition, those models can supply mathematical and physical insights into the phenomenon's nature, giving a better understanding, providing generalist views and thus, making possible valuable innovation.

Up to today, a lot of efforts has been made to typify different aspects and qualities of the Internet traffic: flows [1–3], TCP connection arrivals [4], size of FTP files [5], Web transfers [6], etc. However, there are few works focused on modeling the user itself [7, 8]. In fact, there is not much perspective of the Internet as a collection of multiple human-driven agents (partially due to its size and ever changing nature). As a consequence, this could be an interesting perspective, specially if it could shed some clues of globally efficient, emergent or self-organized behavior.

From this point of view, this paper describes the process of Traffic Analysis and Modeling of an Internet Access Link taking the user as a reference. We consider the campus Network of the Public University of Navarre (UPNA). It represents a Local Network connected to the Internet with a typical and heterogeneous traffic profile and a community of several thousands of users. We explore the use of the Internet Access Link and infer a new statistical user model based on the probabilistic traffic demand observed for individual users. In order to identify the characteristics and origins of this particular model, an statistical data analysis is further performed.

The paper is structured as follows. Section 2 describes the measurement environment and the traffic traces collected for this work. Section 3 discusses the global behavior observed in the Network and reveals the co-existence of different patterns of behavior in the users' community. Section 4 presents the mathematical modeling applied to each of these patterns (or types of users). And as a conclusion, Sections 5 and 6 obtain the global model and discusses its significance.

2 Measurement Environment

We consider the campus Network of the Public University of Navarre (UPNA) in Pamplona (Spain), which is connected to the Internet by two Access Links coming out from a border router. At the time of the measurements (Dec.-2003 and Apr.-2004) those were two ATM OC12 links with a normal use of 10% of the Bandwidth and peaks of 25%. There were a minimal set of filters active in the firewall rules for specific applications: specially for applications designed for use in the local network, some security limitations on the Mail (SMTP), and an incipient filtering on individual ports trying (unsuccessfully) to prevent Peer-to-Peer traffic). Therefore, a mostly unrestricted access to the Internet was granted for every user.

A passive network monitor, placed in the Fast Ethernet Link to the border router, was used to sniff and record the traffic packets on normal operation of the Network. Software-based measurement tools were used to passively copy the traffic and build a trace file. The measurement environment is described in Fig. 1 with the details of downstream and upstream directions for the captured traffic.

It consists of a fast-ethernet hub and a commodity workstation with GNU/Linux Operating System and the Packet Capture Library (Lib-pcap, [9]) installed, to provide packet capture capability. A validation is performed on these tools to ensure that no packet losses occur during the process. The post-process data analysis is done by means of ad-hoc developed applications. The details of the collected packet traces can be seen in Table 1.

They comprise 5 complete (24 hours/each) normal working days, belonging to two different periods of the year (Dec.-2003 and Apr.-2004) in order to also measure the time evolution of the model. These traces involved 728.36 Mill. of IP Datagrams and 316.08 Gigabytes of Total Traffic. The data bytes in the IP Datagrams include the counting of the header bytes.

Fig. 1. Details of the Measurement Scenario.

Day	Date	MDtg(Down)	GBytes(Down)	MDtg(Up)	GBytes(Up)
1	We 2003/17/12	71.06	41.86	62.58	18.80
2	Th 2003/18/12	79.21	44.79	67.69	19.32
3	Mo 2004/19/04	68.75	43.31	68.02	20.55
4	Tu 2004/20/04	74.31	42.69	89.33	22.40
5	We 2004/21/04	71.73	41.05	75.65	21.26
—	Total Traffic	365.07	213.73	363.28	102.35

Table 1. Detail of traffic traces used in the study. The Number of IP Datagrams (in Millions, MDtg) and the amount of Bytes (in Gigabytes, GBytes) are given for each day of measurement.

The monitored traffic presents a standard time profile and composition, with typical daytime patterns of activity, TCP protocol predominance (98% of total traffic Bytes) and asymmetric traffic (70% Downstream, 30% Upstream). As a consequence, the community under study shows some characteristics that are typical of an ordinary community of users [10], a medium-sized Intranet connected to the Internet in flat rate mode.

3 Traffic Analysis in the Community of Users

3.1 The Global View

First, the global behavior of the entire population is analyzed. As it was shown in Section 2, TCP comprises the most significant load of traffic registered. Moreover, total traffic is dominated and shaped by the download component. These effects will lead us to focus on TCP downstream traffic for modeling.

If the whole community of users is ordered according to their daily traffic activity, we obtain an enlightening global picture (see Fig. 2).

Fig. 2. (a) Bytes of TCP traffic registered per user on Thursday 2003/18/12 (total, down and upstream components)(b) Downstream Bytes of TCP traffic registered per user for all days.

Fig. 2a shows the TCP traffic registered per user on Day 2 with its downstream and upstream components. Here, the dominance of the downstream component over the total traffic amount is observed, the same way as the upstream is found to have a minor weight. Users are ordered in the horizontal axis according to their traffic loads (total, down or up respectively). Thus, the first user on this axis is the user with the heaviest traffic activity and user number 4608 is the user with the lowest activity in the community. These users can be different persons for each component, as the most intensive user in the Download is typically a different person than the most intensive user in the Upload component.

Fig. 2b shows the TCP traffic downloaded per user and day for all traces (2 days in Dec.-2003, depicted in blue and 3 days Apr.-2004, shown in red). A positive drift is observed in the consumption among the traces spaced in four months, but the shape of the plots remains constant. Total and Upstream traffic are removed from this figure for clarity but they also show similar shapes in all traces.

Two main characteristics are observed in Fig. 2:

- 1.- Two inflection points and three different regions become visible in the graphics (Fig. 2b). The first point is found at the value of around 30 MB/day for all traces, and the other one at the values of 10 or 30 KB/day for Dec.-2003 or Apr.-2004, respectively. The three areas are found in all the traces. A longitudinal variation gives information of a tendency of increasing consumption for the lighter users as months pass, but the shapes of the curves remain constant for the whole community. Each inflection point represents a mark at which the behavior of users' consumption changes dramatically. These findings reveal that somehow all users don't behave uniformly. In fact, they can be classified in three clusters of different statistical behavior, as we show in the next sections.

2.- A great number of users don't generate traffic (0 Bytes/user/day in the upstream). In Fig. 2a, it can be seen that users beyond number 1688 do not show any uploaded traffic. Their IP addresses register download traffic because they were automatically traced from the Internet by different applications (like spiders, etc.) but they never responded. This leads us to consider that they are not real users, but just unallocated IP addresses or unconnected machines in the Network. These IP addresses are eliminated from our study.

3.2 Searching for Patterns of Behavior

As a second step, we analyze users' behavior during each day of the five collected traces. The main statistical magnitudes of downloaded TCP traffic for users within of the three regions of consumption are obtained. These different groups of users have invariant patterns for each one of the analyzed days. We refer to these groups as Type A, Type B and Type C users, for the regions of the heaviest, the medium and the lightest consumers, respectively. The data displayed in Tables 2 and 3 show the invariance of the behavior in all traffic traces in terms of number of users, downloaded traffic per day and behavior during the day.

<i>Object</i>	<i>Statistical Magnitude</i>	<i>Day 1</i>	<i>Day 2</i>	<i>Day 3</i>	<i>Day 4</i>	<i>Day 5</i>
<i>Total Users</i>	<i>Number of Users</i>	1727	1688	1782	1766	1775
<i>Total Traffic</i>	<i>Downloaded GBytes</i>	40.60	41.37	42.40	41.63	40.35
<i>TYPE A</i>	<i>% Users</i>	7,01%	8,12%	8,36%	7,42%	7,94%
	<i>% Download</i>	87,07%	87,48%	82,60%	84,41%	85,44%
	<i>< X ></i>	89MB	78MB	63MB	91MB	75MB
	<i>σ</i>	541MB	527MB	472MB	422MB	366MB
<i>TYPE B</i>	<i>% Users</i>	65,32%	66,59%	67,62%	66,25%	63,83%
	<i>% Download</i>	12,92%	12,52%	17,39%	15,57%	14,54%
	<i>< X ></i>	2.08MB	2.01MB	3.04MB	2.72MB	2.55MB
	<i>σ</i>	6.57MB	6.69MB	7.69MB	7.30MB	6.75MB
<i>TYPE C</i>	<i>% Users</i>	27,68%	25,30%	24,02%	26,33%	28,23%
	<i>% Download</i>	0,01%	0,004%	0,01%	0,01%	0,01%
	<i>< X ></i>	4.47KB	3.11KB	10.69KB	7.77KB	7.79KB
	<i>σ</i>	1.53KB	1.65KB	6.55KB	7.03KB	6.77KB

Table 2. Main statistical magnitudes obtained for each region show stability over time. These magnitudes are: the distribution of number of users and traffic consumption in each region (expressed as a percentage of the total magnitudes for each day) and the levels of consumption per user and day, expressed as the mean value $\langle X \rangle$ and the standard deviation σ of the downloaded traffic (Bytes) for the cluster of users in every region.

In Table 2 we show that the number of users in each of the three regions of Fig. 2 and its global consumption per day are almost invariant for all traces. These magnitudes are expressed as a percentage over the total number of users

and total bytes of traffic per day, in order to make it clearer. This is also true for the levels of mean consumption per user and day and the standard deviation of the statistical sample. So, each type of user represents a group of individuals that is almost constant in number and traffic demanded per day.

Table 3 describes the pattern of consumption for each group during day 1 (Wednesday 2003/17/12). This is another invariant property observed in the registered traces and it shows a characteristic daytime pattern for each group. In region A, users have a constant and heavy demand over day and night. Users in region B show a stronger consumption in the mornings. In region C the traffic registered is very low and similar during the whole day.

<i>Type of User</i>	<i>Morning (9h/13h)</i>	<i>Afternoon (13h/18h)</i>	<i>Total Day (9h/18h)</i>	<i>Night (18h/9h)</i>
<i>TYPE A</i>	26,63%	27,82%	54,45%	45,55%
<i>TYPE B</i>	41,16%	32,75%	73,91%	26,09%
<i>TYPE C</i>	28,25%	23,14%	51,39%	48,61%

Table 3. Distribution of consumption during Day 1 (Wednesday 2003/17/12) for the three observed groups. The daily distribution of downloaded traffic can be observed in its day-night composition. Also the day components are disaggregated with the morning-afternoon detail.

3.3 Three Clusters of Users

The analysis sketched in the previous subsection gives us the portrayal of a community with three different types of users (A, B and C) coexisting in the Internet Access. Clustering them in three different groups allows us to highlight the size disparity in traffic consumption. Size disparity is often called the “*mice-elephants*” phenomenon, traditionally observed in Internet flows (according to duration or bit-rate), but also referred as volume of traffic [11]. An object is labeled as *mouse* if it contributes to the number of total objects of an ensemble, *elephant*, if it contributes to the total volume mass and in [12] hosts in between are called *mules*. Finally we name each type of users after this terminology. The main features of each group are:

1. Type A users (or *ELEPHANTS*): They are the great consumers, with a heavy and timely constant demand of Internet traffic. They take the 90% of the total traffic (see Table 2), and they have a continuous activity during the day, with almost 50% traffic at night and 50% at day (see Table 3).
2. TYPE B users (or *MULES*): They are the pragmatic users. Their activity on the net matches with business hours of activity. It takes place more intensively in the mornings (41%, see Table 3), and the total amount of day load is almost the 75% of their total download. It seems that they use the Internet Access as a working tool.

3. TYPE C users (or *MICE*): They are the erratic and vanishing users with an extremely low and sporadic demand of traffic, and random daily patterns difficult to be tracked. The total amount of traffic demanded by these users is residual (see Table 2). The consumption is very small and it has the same residual weight at day and at night, almost 50% traffic at night and 50% at day (see Table 3).

This community seems to follow the Pareto Principle or the “80-20 rule”, which says that, when something is shared among a sufficiently large set of participants, there will always be a number k , such that $k\%$ of the resources is taken by $(100 - k)\%$ of the participants. In our case, $k=90$, meaning that the 10% of the population (the *ELEFANTS* group) is responsible for the 90% of the downloaded traffic. For the rest of the users, medium consumers (*MULES*) are the 65% and they make a businesslike use of the resources, taking almost the rest of the bandwidth ‘pie’. Low consumers (*MICE*) contribute only in numbers, the 25% of the total, and they have residual and apparently random traffic demands.

Let us remark at this point that many complex systems present similar generic features that include the Pareto-like statistical behavior. The most popular examples can be found in areas such as econophysics (e.g., distributions of wealth or income in western economies or standardized price returns on individual stocks markets, Company size distribution [13–15]), social networks (e.g., size distribution of human settlements, frequency of human relations [16, 17]), scale-free networks (Epidemic spreading and transportation dynamics [19, 20]), natural phenomena (e.g., Gutenberg-Richter law of earthquake magnitudes [18]), or Biology (protein sequence length distribution [21]). Hence, some similarities appear between all these systems and the distribution of downloaded Internet traffic for users of an Intranet.

4 Models for the Users’ Downloaded Traffic

As explained before, the particular users conducting alike are grouped in three different clusters and a mathematical model is built here for each region of Fig. 2b. Thus, the global model will be obtained as the mixture of three different users’ models.

If the real-valued random variable X represents the amount of incoming TCP traffic that a user consumes per day, expressed in bytes, the downstream traffic belonging to each group is used to build three different Cumulative Distribution Functions (CDFs). In our case, X attains discrete values x_i , with probability $p_i = p(x_i) = P(X = x_i)$. The values of p_i are calculated as the number n_i of users that consumed x_i bytes divided by the number N_c of total of users in the same cluster.

$$F(x) = P(X \leq x) = \sum_{x_i \leq x} P(X = x_i) = \sum_{x_i \leq x} p(x_i) = \sum_{x_i \leq x} \frac{n_i}{N_c}. \quad (1)$$

As we are interested in the probability that a user downloads more than x bytes/day, we will work with the Complementary Cumulative Distribution

Function (CCDF), which is defined as:

$$F_c(x) = P(X > x) = 1 - F(x). \quad (2)$$

In the next subsections, we select three CCDFs to model the downstream TCP traffic for each different group and we fit our monitored real data to these CCDFs. We will begin with TYPE A users, continue with TYPE C and end up with TYPE B users, for they are going to build the bridge between the two extremes.

4.1 Model for Type A Users

This cluster represents around the 10% of total users, consuming almost 90% of the traffic (see Table 2). It follows the Pareto Principle. If we move in the x-axis towards user number one in Fig. 2b, it can be seen a staggering increase in the traffic demand per user. So a fast variation is observed only for this cluster and intuitively could give some clues of a long-tail behavior in the CCDF. If we plot the measured CCDF data in a double logarithmic plot we observe a straight line arrangement for the data-points, which is consistent with a power-law dependence. Based on these observations, a Pareto distribution is used to model this group.

$$F_c(x) = b * x^{-\alpha}, \quad b \geq 0, \quad \alpha \geq 0, \quad x \geq b^{\frac{1}{\alpha}}. \quad (3)$$

A double logarithmic plot for the 5 days is done in Fig. 4 to show the details of the fitting. The data follow a two straight line arrangement and the approach of fitting the empirical data to two Pareto distributions is selected, as it seems to be more general and complete than selecting a truncated Pareto as CCDF (see [20]).

The first line of data is labeled as “Pareto 1” in Fig. 3a and 3b and appears in the area of transition between TYPE A and TYPE B users. This transition exists because the threshold value that separates regions A and B (30MB/user/day) is a point, that is chosen among an area of inflexion points.

The result of finding two straight lines and no just one, indicates that there is not a well-defined threshold or boundary that separates TYPE A users from the rest (observed in [17]). It also indicates that there are two speeds of consumption within the *ELEPHANTS* herd, as the power law behavior has different characteristics in each distribution. The “Pareto 1” zone has an exponent $\alpha < 1$ and the value of α for the “Pareto 2” is around 2. Table 4 shows the details of the fitting parameters.

These users consume a heavy load of traffic every day. Consumption varies in a wide range between users (10 GBytes and 30 MBytes per user and day). In Table 2 the mean value of incoming traffic is around 80 MBytes/user/day but with a high dispersion value, typical of long-tail distributions (the standard deviation for this population is around 400-500 MBytes, revealing a high spread of its values). They are always on-line and perform an intensive use of the link, with a constant and uniform traffic profile over day and night (see Table 3).

Fig. 3. (a,c,d,e,f) Graphic details of the fittings for ELEPHANT users in double logarithmic plot for all the traces. (b) Empirical and fitted CCDF obtained for day 1.

<i>DAY</i>	1	2	3	4	5
b_1	7143.08	44700.9	19500.0	18613.8	10242.7
α_1	0.519	0.630	0.578	0.576	0.541
b_2	$1.45E + 16$	$1.25E + 24$	$1.09E + 19$	$9.25E + 15$	$8.06E + 24$
α_2	1.944	2.842	2.272	1.928	2.92

Table 4. Values of the fitting parameters b and α obtained for the five days in the two zones “Pareto1” and “Pareto2”.

They download high quantities of data, probably heavy Web- or FTP-files, or even they can be connected to P2P networks.

4.2 Model for Type C Users

Users belonging to this group consume a residual quantity of traffic, with random and irregular patterns of activity (see Table 2 and 3). They show a better marked mean consumption than *ELEPHANTS*, and plotting the measured CCDF data in a natural logarithmic plot a straight line arrangement appears for the data-points, which is consistent with an exponential dependence. Finally the exponential distribution is used to model this group:

$$F_c(x) = be^{-ax}, \quad a \geq 0, \quad x \geq 0. \quad (4)$$

Fig. 4 shows the details of the fitting in a plot that represents y-axis in natural logarithm for the 5 days. Table 5 shows the details of the fitting parameters.

The volume of consumption of *MICE* is so low that one could question the worth of modeling them. But let us recall that it is an important population

Fig. 4. (a,c,d,e,f) Graphic details of the fittings for *MICE* users in natural logarithm plot for all days. (b) Empirical and fitted CCDF obtained for day 1.

DAY	1	2	3	4	5
<i>a</i>	$6.37E - 4$	$1.50E - 4$	$1.49E - 4$	$6.05E - 4$	$1.43E - 4$
<i>b</i>	7.32	2.41	1.61	3.01	1.53

Table 5. Values of the fitting parameters *b* and *a* obtained for the five days

within the Network, around the 25% of the users belong to this group. They contribute to the number of entities but not to the volume. The demand of traffic is below tens of KBytes/user/day, with a weak tendency of growth as time passes, from threshold values of 10KB in Dec.-2003 to 30KB in Apr.-2004 (see Fig. 2b). This means that just a hundred of packets (40-1500 bytes long) have been received per day by one of this users, typical for sporadic surfing or mail applications activities.

4.3 Model for Type B Users

Most users belong to this group (approximately 65%, see Table 2). Their consumption lies somewhere in between the last two extremes. The Weibull distribution can offer a way of transition from an exponential to a heavier-tailed distribution with a shape parameter ($\beta < 1$), and it is found in literature that some empirical distributions are often close to this type of distribution [11]. Hence, a Weibull distribution is selected in this case as CCDF, due to its flexibility and because it can mimic a transition from the exponential to the Pareto distribution.

$$F_c(x) = e^{-ax^\beta}, \quad a \geq 0, \quad \beta \geq 0, \quad x \geq 0. \quad (5)$$

The details of this approximation are shown in Fig. 5 in a logln-log plot that represents the decimal and natural logarithm of $F_c(x)$ in the y-axis and the decimal logarithm of x in the x-axis for the 5 days of data collection. Table 6 shows the details of the fitting parameters.

Fig. 5. (a,c,d,e,f) Graphic details of the fittings for *MULE* users in logln-log plot for all days. (b) Empirical and fitted CCDF obtained for day 1.

DAY	1	2	3	4	5
a	$7.08E-5$	$3.59E-5$	$3.33E-5$	$3.62E-5$	$3.17E-5$
β	0.633	0.663	0.675	0.678	0.676

Table 6. Values of the fitting parameters b and a obtained for the five days.

This group of users belong to an intermediate kind (see Table 2), with a moderate consumption of traffic and use of the Internet access. A *MULE* digests a traffic load in the range of tens of KBytes to tens of MBytes per user and day, showing a growing tendency for the lighter consumers as time passes. The average demand per user is around 2 or 3 MBytes/user/day (in Dec.-2003 and 7 in Apr.-2004, respectively) and the dispersion value is high (the value of the standard deviation is around 6-7 MBytes/user/day), getting closer to the *ELEPHANT*'s profile. It is also observed in Table 3 that they concentrate their activity in business hours, possibly using the Internet Access in their work activities. These users seem to read emails, make sporadic surfing on the net and download relatively light Web pages or files (email attached or FTP).

5 The General Model

We proceed now to propose a statistical user model to describe the incoming traffic in the Internet Access for the general community. This is the result of the combination of the three models which were obtained for each type of user.

The CDF function $F(x)$ for this global model is plotted in Fig. 6, showing the empirical data registered on Day 1 (Wed. 2003-17-12) and the theoretical distributions fitted to these data. This global CDF represents the probability that a user demands less than an specific traffic load. This probability is calculated from the CDF for the type of user (or region of consumption) averaged by the relative weight of this type of user in the community (averaged by the number of users of each type shown in Table 2).

Fig. 6. (a) The general model built from the combination of the individual models for each type of user (empirical data and model curves). The x-axis is in logarithmic scale. (b) Details of the *ELEPHANTS* region. The two Pareto CDF approach used in the fitting procedure can be observed here. (c) Details of the *MULES* region. (d) Details of the *MICE* region.

The three different groups of users are very well identified in the general model. We can think of the Network as a multi-agent system in an active environment. At first sight, the agents could seem to be in a weak competition for the bandwidth in the Internet Access, but it is more realistic to think that they are non-interacting agents without any mutual information among them. Even under these circumstances, and surprisingly, the system self-organizes with the pattern of behavior given in Fig. 6.

The part of the population that receives the highest traffic income, generally less than 10% of the individuals, follows a power-law distribution (Pareto behavior). This means that the consumption is dominated by a few individuals and, for the misfortune of planning engineers, that there always exists a significant probability or risk of finding a more intensive user in the Network. In the range of low traffic download, the cumulative distribution follows the Boltzmann-Gibbs

law (exponential behavior with $F_c(x) \propto \exp(-x/T)$). Hence, by analogy with statistical physics, one may expect that the activity of these users is characterized by some kind of random access to the Net (memoryless), where the effective traffic ‘temperature’ (with $T = 1/a$ in Table 5) would be related to the average amount of bytes consumed per agent.

Let us remark that these two regimes, the Pareto and the Boltzmann-Gibbs statistical patterns, can be found in other real systems which also depend on the human behavior, such as the distribution of wealth or income in the western societies [13]. But also a third different regime is observed here, namely the group of medium consumers or *MULES* described by the Weibull distribution function. This distribution can model the transition from an exponential to a heavier-tailed distribution by varying its shape parameter ($\beta < 1$). The low traffic demand dominates this group, but the consumption increases rapidly for the last users that are close to the Pareto-like region.

Summarizing, the model depicted in Fig. 6 collects and brings out all the information needed for the statistical forecasting of consumption that a community of users in a Intranet will perform of the Internet Access Link. As it is, it could also be useful for TelCos, to investigate new strategies in Network Planning or Marketing areas of Internet consumption.

6 Conclusions

This work describes the process of Traffic Analysis and Modeling of an Internet Access Link taking the user as a reference. A new probabilistic global model is obtained to describe user traffic consumption in terms of bytes per user and day.

Considering the Network as a multi-agent system, an emergent statistical structure is found for the Internet demand within the community. The identification of three different groups of users and the probabilistic distributions that describe their behavior have been established.

Some particular properties are present in these experimental results. Apart from the usual Pareto and Boltzmann-Gibbs behaviors, which are also found in other multi-agent systems commanded by the human action, a new emergent regime is found here. This can be modeled by the Weibull distribution, that could be interpreted as a bridge between the Pareto and the Boltzmann-Gibbs regimes.

Let us stand out that different models and real systems with dynamical processes and local interactions taking place at the microscopic scale show similar macroscopic characteristics to those observed in this work. This similar pattern of behavior, that continues to emerge in our analysis, is somehow striking since it would be more realistic to think that the agents are independent and non-interacting when they access to the Internet link.

We hope that the findings presented in this paper will help for a better understanding of the laws governing the interactions in multi-agent systems, and that they will provide empirical views to achieve enhanced modeling for complex systems.
